METAL PARTICLES SIZE INFLUENCE ON GRADED STRUCTURE IN COMPOSITE Al2O3-Ni

VPLIV VELIKOSTI KOVINSKIH DELCEV NA GRADIENTNO STRUKTURO KOMPOZITA Al2O3-Ni

1 INTRODUCTION

Novel ceramic-metal composites should have a combination of properties such as good strength, high hardness together with high fracture toughness, wear and thermal resistance as well as chemical inertness, among others. Such demands may be fulfilled by functional graded materials (FGM). These materials are characterized by a variation in composition and structure gradually over volume, resulting in corresponding changes in the chemical and physical properties of the composite.1,2

The concept of graded materials was shown for the first time in 1971 in an article entitled “Preliminary work on Functionally Graded Materials”.3 However, other in-situ techniques such as: spray forming,4,15 centrifugal casting1,6,19 and the deposition methods of Electrothermic Deposition (EDP)5,20-26 and Pulsed Laser Deposition (PLD)27,29 have also gained broad attention.

Ceramic-metal composites with a gradient concentration of the metal particles are an example of FGM materials. Typical scheme of ceramic-metal FGM composites is shown in Figure 1. Such composites can be used as functional materials, and also as structural materials in the aerospace industry.

The principal advantage of ceramic matrix composites with metal particle concentration gradients is an increase of the fracture toughness with respect to the ceramic matrix.29-31 The literature data indicate that the particle size and amount of the metal phase essentially affect crack propagation.32 Modification of the particle size or particle size distribution may influence the composite performance and the properties of the materials.

The aim of this study was to investigate the effect of the nickel particle size on the changes in metallic phase content in the graded structure in the Al2O3-Ni composites. Centrifugal slip casting was chosen as the method of composite fabrication. This method allows the creation of a graded distribution of Ni particles in the hollow cylinder composite sample. Functional graded materials were prepared in the vertical rotation axis. In the experiments the following powders were used: α-Al2O3 TM-DAR from Taimei Chemicals (Japan) of an average particle size 0.133 μm and density 3.96 g/cm3 and Ni powders from Sigma-Aldrich of an average particle size 0.133 μm and density 3.96 g/cm3 and Ni powders from Sigma-Aldrich of an average particle size 3 μm and density 8.5 μm. Aqueous slurries containing alumina (50 % of volume fractions of solid phase volume content) and nickel powders (10 % of volume fractions) were tested. Deflocculates diammonium citrate (p.a., Aldrich) and citric acid (p.a., POCH Gliwice) were also added. Final sintering was conducted on all the specimens at 1400 °C in a reducing atmosphere (N2/H2). The obtained samples were characterized by X-ray diffraction (XRD) and scanning electron microscopy (SEM). In addition, quantitative analyses of the Ni particles distribution were made. In the fabricated samples the graded structure were characterized by zones with different Ni particles concentration. The size of the Ni particles influences the width of these zones. Vickers indentation was used to determine the hardness of the materials.

Keywords: functionally graded material (FGM), centrifugal slip casting (CSC), Al2O3-Ni system

Namen študije je bil preiskati vpliv velikosti delcev niklja na spreminjanje vsebnosti kovinske faze v gradientni strukturi kompozita Al2O3-Ni. Centrifugalno oblikovalno ulivanje je bilo izbrano kot metoda za izdelavo kompozita. Ta metoda omogoča stopenjsko razporeditev delcev Ni v votlem cilindričnem kompozitnem vzorcu. Funkcionalno razporejen material je bil izdelan na vertikalni rotacijski osi. Za preizkuse so bili uporabljeni naslednji prahovi: α-Al2O3 TM-DAR iz Taimei Chemicals (Japan) s povprečno velikostjo delcev 0.133 μm in gostoto 3.96 g/cm3 ter prah Ni iz Sigma-Aldrich, s povprečno velikostjo delcev 3 μm in 8.5 μm. Preizkušena je bila na vodi osnovana mešanica (z vsebnostjo 50 % volumenskega deleža trdne faze), ki je vsebovala prah glinice in niklja (10 % volumenskega deleža trdne faze). Uporabljali so deflokkulanti (diamonium citrat (p.a., Aldrich) in citric acid (p.a., POCH Gliwice)), ki so omogočali razporeditev Ni delcev in sprostali površino aluminija za potrebe sinteriranja. Na sinteriranih vzorcih je bila izvedena tudi kvantitativna analiza razporeditve Ni delcev. V vzorcih je bila analizirana gradientna struktura po področjih z različno koncentracijo Ni delcev. Velikost Ni delcev vpliva na izkazane rezultate. Določena je bila trdota materiala po Vickersu. Ključne besede: funkcionalno gradientni material (FGM), centrifugalno oblikovalno ulivanje (CSC), Al2O3-Ni sistem
size of metal in the composite enables precise control of the material properties.

In the present work, Al₂O₃-Ni composites with a concentration gradient of the metal particles were fabricated using centrifugal slip casting. This method allows fabrication of a graded distribution of Ni particles in a hollow cylinder composite sample. The aim of this study was to investigate the effect of the nickel particle size on the metallic phase content in graded Al₂O₃-Ni composites.

2 EXPERIMENTAL PART

2.1 Materials and methods

In the tests the following powders were used: α-Al₂O₃ TM-DAR from Taimei Chemicals (Japan) of an average particle size \(D_{50} = 0.133 \, \mu m\) and density 3.96 \(g/cm^3\) and Ni powders from Sigma-Aldrich of average particle sizes \(D_{50} = 3 \, \mu m\) and \(D_{50} = 8.5 \, \mu m\). For both Ni particle sizes a series of composite samples were prepared. Aqueous slurries containing alumina (with 50 % of volume fractions content of solid phase) and nickel powder (10 % of volume fractions with respect to total volume) were tested. Deflocculates diammonium citrate (p.a., Aldrich) and citric acid (p.a., POCH Gliwice) were also added. Figure 2 shows the scanning electron microscopy images of α-Al₂O₃ and the two Ni powders.

The components were homogenized in a planetary mill with a rotation speed of 300 min⁻¹ for 90 min. Afterwards, the air absorbed on the particle surfaces was removed in a THINKY ARE-250 Mixer and Degassing Machine for 15 min at a speed of 900 min⁻¹. The equipment allows the removal of bubbles above 1 \(\mu m\). The ceramic water-based slurries were cast into thick-walled tubes using a plaster mold. A stirrer with a vertical rotation axis was used in the centrifugal slip casting process. The process parameters were first chosen by set of trials. The dimensions of the fabricated tubes are as follows: the outer radius is 20 mm, the length 40 mm and thickness 18 mm. Thereafter, the samples were dried and removed from the plaster mold. The final step was sintering which was conducted on all specimens at 1400 °C in a reducing atmosphere (\(N_2/H_2\)).

An X-ray Rigaku MiniFlex X-ray diffractometer II was used to study the structure of the composites. The data were recorded using the "step-scanning" method in the 2θ mode with Cu-\(K_{\alpha1}\) radiation.

The Al₂O₃-Ni composites microstructures were characterized using a SEM HITACHI SU-70 scanning...
electron microscope. Quantitative analysis of the graded region microstructures from SEM images was carried out using the Micrometer computer image analysis program.\textsuperscript{33}

The hardness of the microstructures from outer sample to inner sample were measured with a Vickers hardness tester. The hardness measurements were made under a load of 49.03 N.

**3 RESULTS AND DISCUSSION**

Figure 3 shows typical examples of fabricated tubes before and after sintering. Using the Archimedes method, it was found that the average sintering shrinkage was about 13%. A tube having a post-sintering diameter of 17 mm, inner radius 6.5 mm and 40 mm could be fabricated successfully (i.e. without breakage of the cast tubes during subsequent drying and sintering) with a relatively high consolidation (> 98.8 % of relative density). No damage in the form of cracks or voids on the surface of samples were noticed. The X-ray data from the surfaces and the cross-sections of composites confirmed the presence of the two phases Ni and Al$_2$O$_3$.

Figure 4 presents an typical diffraction pattern.

In Figure 5 the graded distribution of metal particles in Al$_2$O$_3$-Ni composites is shown. The grey area is Al$_2$O$_3$ and the bright area is Ni. Three zones of Ni particles of the samples can be distinguished in the cross-section. A quantitative analysis of the photomicrographs using the Micrometer computer image analysis program\textsuperscript{33,34} yielded the compositional profile variations shown in Figure 6. The measurements show that in area A, the nickel particle content was equal to 12 % of volume fractions per 1 mm width in both samples. Between areas A and B there is a mild increase in nickel particles. In area B there was a maximum of nickel particles in both composites. In the case of the nickel powder with the larger particle size ($D_{50} = 8.5 \mu m$) it was observed that zone B is narrower than zone A. In area B there was a maximum of nickel particles equal to about 28 % of volume fractions per 560 μm wide for the sample prepared using Ni $D_{50} = 8.5 \mu m$ powder. In contrast, the sample prepared using a Ni powder ($D_{50} = 3 \mu m$) was contained 25 % of volume fractions per 840 μm. Then there was a sharp decline in nickel particles. However, in area C there was a mild decrease, down to 0 % of volume fractions, in the percentage of nickel particles.

The motion of metal particles in a slurry under centrifugal force can be determined by Stokes’ law.\textsuperscript{35} According to this law the velocity of the particles is proportional to the square of the particles’ diameter. Therefore the migration distance is greater in the case of larger particles. For this reason the width of zone B is smaller in the case of samples prepared with 8.5 μm Ni than for composites with 3 μm Ni powder.

The hardness values measured from the outer to the inner periphery are shown in Figure 7. It has been found that the hardness profiles for both series (3 μm and 8.5 μm Ni powders) have similar behaviour (Figure 8). In region A hardness values in the range 1000-1300 HV are found for both series. Region A results from the removal maximum of nickel particles equal to about 28 % of volume fractions per 560 μm wide for the sample prepared using Ni $D_{50} = 8.5 \mu m$ powder. In contrast, the sample prepared using a Ni powder ($D_{50} = 3 \mu m$) was contained 25 % of volume fractions per 840 μm. Then there was a sharp decline in nickel particles. However, in area C there was a mild decrease, down to 0 % of volume fractions, in the percentage of nickel particles.

The motion of metal particles in a slurry under centrifugal force can be determined by Stokes’ law.\textsuperscript{35} According to this law the velocity of the particles is proportional to the square of the particles’ diameter. Therefore the migration distance is greater in the case of larger particles. For this reason the width of zone B is smaller in the case of samples prepared with 8.5 μm Ni than for composites with 3 μm Ni powder.

The hardness values measured from the outer to the inner periphery are shown in Figure 7. It has been found that the hardness profiles for both series (3 μm and 8.5 μm Ni powders) have similar behaviour (Figure 8). In region A hardness values in the range 1000-1300 HV are found for both series. Region A results from the removal
of fluid through capillary action in the plaster mold. In Figure 7 a slightly lower hardness is observed in the area between A and B due to the increase of nickel particles in the composite. The maximum amount of nickel particles in the region B corresponds to the lowest hardness values. This part of the sample was produced as a result of centrifugal acceleration. As expected, in both series of samples the maximum hardness values are observed in region C, at the inner edge of the casting due to the absence of nickel particles. The area C in both samples corresponds to hardness values in the range 1800-1920 HV.

4 CONCLUSIONS

Al$_2$O$_3$-Ni FGM ceramic matrix composites with a graded distribution of Ni particles have been successfully produced by the centrifugal slip casting method.

Quantitative analysis of the graded microstructure in the composites revealed that the graded zones depend on the size of the starting metal particles in the slurry.

By changing the content of the metallic phase it is possible to control the hardness profile. As a result of the centrifugal slip casting method used, the packing of the powder particles prevents grain growth.

Acknowledgments

The authors would like to thank Professor M. Szafran and his Team from the Faculty of Chemistry of Warsaw University of Technology for help in preparing the samples. The results presented in this paper were obtained as part of the the Polish National Science Centre (NCN) project No. 2013/11/B/ST8/0029.
